Sequence of figwort mosaic virus DNA (caulimovirus group)

Richard D.Richins, Herman B.Scholthof and Robert J.Shepherd

Department of Plant Pathology, University of Kentucky, Lexington, KY 40546, USA

Received August 21, 1987; Revised September 9, 1987; Accepted September 18, 1987

ABSTRACT

The nucleotide sequence of an infectious clone of figwort mosaic virus (FMV) was determined using the dideoxynucleotide chain termination method. The double-stranded DNA genome (7743 base pairs) contained eight open reading frames (ORFs), seven of which corresponded approximately in size and location to the ORFs found in the genome of cauliflower mosaic virus (CaMV) and carnation etched ring virus (CERV). ORFs I and V of FMV demonstrated the highest degrees of nucleotide and amino acid sequence homology with the equivalent coding regions of CaMV and CERV. Regions II, III and IV showed somewhat less homology with the analogous regions of CaMV and CERV, and ORF VI showed homology with the corresponding gene of CaMV and CERV in only a short segment near the middle of the putative gene product. A 16 nucleotide sequence, complementary to the 3' terminus of methionine initiator tRNA (tRNA; met) and presumed to be the primer binding site for initiation of reverse transcription to produce minus strand DNA, was found in the FMV genome near the discontinuity in the minus strand. Sequences near the three interruptions in the plus strand of FMV DNA bear strong resemblance to similarly located sequences of 3 other caulimoviruses and are inferred to be initiation sites for second strand DNA synthesis. Additional conserved sequences in the small and large intergenic regions are pointed out including a highly conserved 35 bp sequence that occurs in the latter region.

INTRODUCTION

The caulimoviruses are a group of small double stranded DNA viruses that infect higher plants^{1,2}. The type member of the group, cauliflower mosaic virus (CaMV), has a genome of about 8000 base pairs (bp) with six to eight major genes and one large and one small intergenic region^{3,4,5}. Its DNA can be cloned in bacteria in an infectious form^{6,7}, hence, it is easy to manipulate the virus genetically. As a consequence, CaMV has become a useful model system for studying gene expression and pathogenesis in plants.

Until recently, there has been little information on other members of this group of plant viruses, including figwort mosaic virus (FMV), the subject of this communication. This virus appears to be similar to CaMV both biologically and in having a small double-stranded DNA genome^{8,9,10}.

However, hybridization tests have shown that FMV DNA has little apparent sequence homology with that of $CaMV^{10}$.

Recently, we have adapted a strain of FMV to solanaceous hosts which are more amenable than its original host (<u>Scrophularia californica</u>) to greenhouse, tissue culture and protoplast manipulations ¹¹. In this communication we report the sequence of an infectious clone of this adapted strain and compare it at the nucleotide and amino acid sequence level with CaMV and other sequenced caulimoviruses.

MATERIALS AND METHODS

Standard molecular biology techniques were employed throughout this study (for protocols, see Maniatis <u>et al</u> 12), therefore, only novel or modified procedures will be described.

<u>Virus source and cloning</u>: The original virus, isolated from <u>Scrophularia californica</u>, was adapted to solanaceous plants (DxS strain) as described ¹¹, then its DNA was cloned into the unique <u>SacI</u> site of pUC13. The resulting plasmid, designated pFMV Sc3, was found to be infectious to <u>Nicotiana bigelovii</u>.

<u>DNA sequencing</u>: For the sequencing of the FMV genome, <u>Xba</u>I fragments of pFMV Sc3 were subcloned into M13mp11. Deletion subclones were made for each of the <u>Xba</u>I subclones using the T4 DNA polymerase cutdown method of Dale <u>et al</u> 13. Subclones of the regions flanking each of the <u>Xba</u>I sites and the unique <u>Sac</u>I site were generated by gel isolating specific restriction fragments and cloning them into either M13mp11 or pUC119 (supplied by Jeff Viera, Waksman Institute, Piscataway, NJ).

Reagents and the apparatus (model S0) for the dideoxynucleotide sequencing procedure were purchased from Bethesda Research Laboratories (BRL, Gaithersburg, MD). 35 S-deoxyadenosine $^{5'}$ -(α -thio)triphosphate (New England Nuclear, Boston, MA) was used in place of the 32 P analogue. Procedures used for the phage and template purification and sequencing reactions were from BRL's M13 Cloning/Dideoxy Sequencing Instruction Manual. Two modifications were made in the dideoxy sequencing protocol: 1) The dideoxynucleotide triphosphate concentrations were reduced to allow more bases to be read from a single subclone, and 2) Sequencing reactions were carried out at 43 C instead of 30 C.

<u>Computer analysis</u>: Many of the analyses were performed on an Apple IIe computer in Apple Pascal format using either the University of Minnesota or the Cornell DNA sequence analysis program. The linear amino acid homology

plots utilize a modified version of the Cornell DNA analysis program PROTHOM to give a graphical output of the data derived from the program (this program is available from the authors on request). To aid in the alignment of analogous polypeptide sequences from FMV, CaMV and CERV, the FASTP program (IBM PC version)¹⁴ was used. Two dimensional homology plots were performed on an IBM computer using the DIAGON program¹⁵.

RESULTS

<u>DNA Sequence</u>: The sequence was obtained from independent clones from both strands of the genome such that nearly every section of the genome was represented at least twice, and frequently for three or more times. Approximately 88% of the whole genomic sequence was represented by clones from both strands of the DNA. Only a small region of approximately 100 bp located near the center of ORF IV was represented by data from only one clone. This fragment was very difficult to obtain as a stable bacterial clone for unknown reasons.

The complete nucleotide sequence of the plus strand of the DxS isolate of FMV is given in Fig. 1. The genome consists of 7,743 bp, and has a GC ratio of 43%. In comparison, the genomes of the CM1841 strain of CaMV⁴ (8,031 bp) and carnation etched ring virus (CERV) ¹⁷, another member of the caulimovirus group (7,932 bp), each have a GC content of 44%. We have numbered the FMV sequence beginning with the 5' end of the probable primer binding site (5'-TGGTATCAAAGCCATG-3') because essentially analogous sequences are found at the zero map positions of the CaMV and CERV sequences^{3,4,5,17}. In addition, end-labelling studies performed by Hull and Donson⁹ and in this lab¹¹ confirm that the minus strand discontinuity is located very near this region (Fig. 2).

Coding Regions: Computer analysis of the plus strand predicts seven putative coding regions having molecular weights in excess of 10 kDa (Fig. 2). In addition, there is a 7.4 kDa protein coding region (ORF VII) immediately preceding ORF I (Fig. 2). A large intergenic region between ORFs VI and VII and a small intergenic region between ORFs V and VI, are also present. With respect to size and location, seven of these eight coding regions (ORFs I-VII) and both intergenic regions closely resemble regions found in the CaMV^{3,4} and CERV¹⁷ genomes. ORF VIII, which overlaps the C-terminal portion of ORF IV of the CaMV genome¹⁸, is not found in the FMV and CERV genomes. The FMV genome contains an additional reading frame, designated ORF IX, which overlaps parts of regions III and IV (Fig. 2). The coordinates delineating

Fig. 1. The Nucleotide Sequence of FMV DNA (DxS strain). The plus strand is presented here with the numbering beginning as described in the text and in Figure 5.

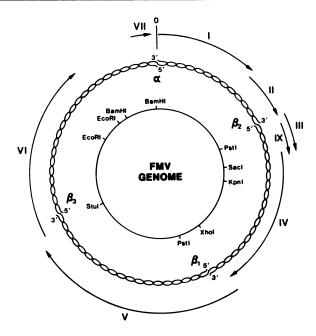

Fig. 2. Organization of the FMV Genome. The inner circle shows the positions of selected restriction sites found in the 7743 bp circular genome. Single-stranded discontinuities are shown in the middle (chained) circle. We have numbered the three single-stranded discontinuities found in the plus strand such that the two discontinuities β_1 and β_2 at positions 1250 and 3300 are numbered the same as those found at these approximate positions in the CaMV genome. The additional discontinuity (at position 5350) is denoted β_3 . The peripheral arrows depict the positions of the major open reading frames and are positioned to show the reading frames in which they occur.

each of these ORFs, together with the molecular weights (MW) and percent direct homologies for the putative translation products of FMV, CaMV and CERV are given in Table 1.

Only two open reading frames of significant size are observed in the minus strand. The predicted MWs of these two translation products are 10,840 and 10,399 Da. However, no sequences associated with transcriptional promoters or terminators were found flanking these ORFs so it seems unlikely that these regions are expressed.

Comparisons of each of the putative FMV and CaMV translation products using the matrix analysis program of Staden 15 are shown in Fig. 3.

ORF I is one of the most highly conserved coding regions in the FMV genome (second only to region V) with nearly 54% of the predicted amino acids being exactly conserved compared to the region I protein of CaMV (Fig 3A). A

Table 1. Protein Coding Regions of the FMV, CaMV and CERV Genomes

function has not yet been identified for this gene product. However, it is expressed in CaMV infected plants 19 , 20 .

ORFs II and III are also conserved in the FMV genome, but with less homology than was observed for ORFs I and V (Fig 3B,C). Gene II of CaMV has been shown to encode an aphid transmission component. 21,22,23 The function of the ORF III protein has not been determined, although this gene of CaMV is expressed in infected plants 24. With only 115 amino acid residues, this region of FMV is the smallest conserved gene.

The ORF IV translation product of FMV shows approximately the same overall degree of homology (vs similar regions of CERV and CaMV) as do ORFs II and III. Near the amino terminus, the ORF IVs of FMV, CERV¹⁷ and CaMV³, 4 encode proteins which are rich in glutamic and aspartic acids. Except for the high proportion of these acidic amino acids throughout this region, there is little additional amino acid homology. The middle third of the FMV region IV protein shows an increased degree of homology with the equivalent region of the CaMV and CERV capsid protein with over 40% of the amino acid sequence

a) Assuming that translation begins with the first in frame ATG and ends with the first in frame stop codon within each open reading frame.

b) The molecular weights of the translation products of ${\tt CERV^{16}}$ and ${\tt CaMV^4}$ are presented for comparison.

c) The numbers in parentheses after each molecular weight is the percent direct homology of the amino acid sequences in each putative coding region.

d) The homologies between region VII were so low that a reliable degree of homology could not be determined. This was also the case when CaMV ORF VII was compared with CERV ORF VII.

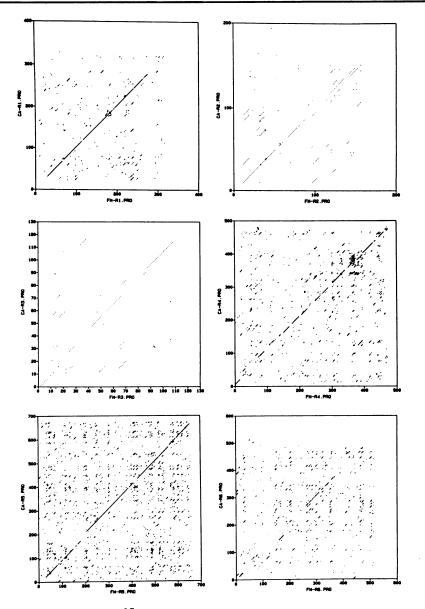

Fig. 3. Matrix analyses 15 comparing six of the major putative translation products of FMV with homologous translation products of the CaMV genome. 4 The translation products of both FMV and CaMV begin from the first methionine in each reading frame and end at the first termination codon (TAA, TAG or TGA). For each analysis, a 'window' of eight amino acids was used with positive matches being given for scores exceeding 96. The comparisons begin with ORFs I in the upper left hand corner and end with ORFs VI in the lower right hand corner.

being conserved. A highly basic domain containing over 40% lysine residues begins at amino acid 316 and ends at amino acid 396. Similar lysine-rich regions are found in $CaMV^4$ and $CERV^{17}$ region IV proteins.

Immediately following this highly basic domain in the putative coat protein gene is a region with a highly conserved array of cysteine residues with the arrangement of: CysX₂CysX₄HisX₄Cys. As pointed out by Covey²⁵, this array is conserved in the gag gene of all replication competent retroviruses and the <u>Drosophila</u> retrotransposon copia. Furthermore, it also appears in the coat protein genes of CaMV and CERV. Beyond this Cys-motif is the C-terminal domain that is rich in glutamic and aspartic acids and serine.

The putative region V protein of FMV shows a particularly interesting homology with its CaMV counterpart. When the inferred amino acid sequences of FMV and CaMV are aligned, the three distinct domains pointed out by Toh et al²⁶ for reverse transcriptases can be distinguished. The first domain is comprised of amino acids 26 through 143 of FMV (18 through 135 of CaMV), has high homology with the avian retroviral gag-specific protease pl5²⁷. The next major domain within the putative region V protein, beginning at amino acid 211 (203 of CaMV) and ending at amino acid 564 (556 of CaMV), together with the next domain (consisting of amino acids 574 through 666 of FMV or 563 through 679 of CaMV), may be the reverse transcriptase²⁶. With retroviruses, it is associated with both RNase H and RNA dependent DNA polymerase activities. The homology between FMV and CaMV within these two domains is about 73% and 68%, respectively. Hence, this is the most highly conserved protein coding regions of these viral genomes (Fig. 3E).

The least conserved coding region of the major genes of FMV and CaMV and CERV is that of region VI. Except for a small conserved tract near the center of the protein, little homology is apparent in this ORF for the three viruses. Although Hull $\underline{\text{et}}$ $\underline{\text{al}}^{17}$ also have found gene VI to have the least homology between CERV and CaMV, they found considerably more homology than is the case for the FMV and CaMV genes.

A graphical plot (Fig. 4) showing the homologies of the deduced gene VI translation products of the three viruses emphasizes the relationships of these putative proteins. Although short tracts of homologous sequences occur near the N-terminus for each of the ORF VI polypeptides, the most extensive region is near the center of the gene. Within this conserved central domain there is a run of 47 amino acid residues which shows 47% homology between FMV and either CaMV or CERV.

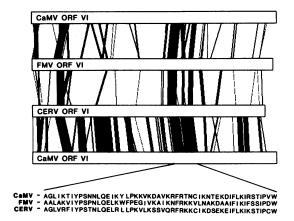

Fig. 4. Graphical plot of the amino acid homologies of ORF VI of FMV with region VI of CaMV and CERV. Homologous regions between polypeptide chains are displayed as dark lines. The plot utilizes a modified version of the Cornell DNA Sequence Analysis Program (PROTHOM) to generate comparisons. A window of 8 amino acids was used for this comparison with homologies exceeding 62% being scored positive. Homologous regions offset more than 25 amino acid residues in either direction along the polypeptide chain were not recorded in the data plot.

Regions VII, VIII (CaMV) and IX (FMV) were also compared, but no significant levels of homology were noted (data not shown).

Noncoding Regions: As noted earlier, two intergenic regions are present in the genome of FMV: a large intergenic region located between ORFs VI and VII consisting of 577 bp, and a small intergenic region located between ORFs V and VI consisting of 117 bp.

Within the small intergenic region there is a TATA-like box implicated in promoter function (TATAAAA) about 70 bp upstream from the ATG start of ORF VI. CG rich regions flank this sequence. Although the virus-specific RNA species occurring in FMV infected plants have not been characterized, it seems by analogy with CaMV that this region serves as a transcriptional promoter for ORF VI.

The large intergenic region contains several short runs of nucleotides homologous with the corresponding regions of CaMV and CERV. A graphical representation of the sequence homologies between the large intergenic regions of FMV, CaMV and CERV is presented in Fig. 5. A sequence similar to the TATA or Goldberg-Hogness box is found in each of the three viruses (see Fig. 5). In the FMV genome the probable TATA box occurs just inside the 3'-

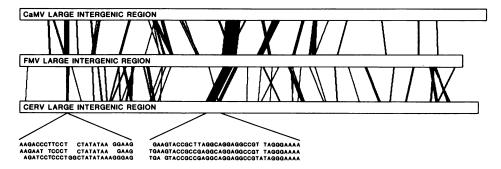

Fig. 5. Graphical homology comparisons of the large intergenic regions of three caulimoviruses (CaMV-top, FMV-middle, CERV-bottom). The comparison starts 100 bp upstream from the proposed TATA box of the genomic-length promoter and continues to the start codon of region I. The program used for this plot is identical to the one described in Fig. 4, except that a window of 10 bp was used and homologies exceeding 80% were scored positive. Regions of homology offset more than 40 bp in either direction were not recorded. The sequence of regions with a high degree of homology are given.

end of ORF VI (at nucleotide 6893). An identical sequence is found in the large intergenic regions of both CaMV and CERV (TATATAA). This sequence is reported to be essential for high level expression of eucaryotic genes including those of plants²⁸. Messing et al²⁹ have made comparisons among the sequences of plant 5'-controlling regions and remarked on the frequent occurrence of the dinucleotide TC preceding the TATA box. This TC dinucleotide is found preceding the TATA boxes of both the FMV and CaMV large intergenic regions. However, the dinucleotide GC precedes the TATA box of the large intergenic region of CERV as well as the TATA box found in the small intergenic region of FMV.

At position 7064 of FMV a sequence associated with polyadenylation of mRNA (AATAAA) occurs. This sequence lies 162 bp downstream from the inferred FMV TATA box. For comparison, the possible polyadenylation sequence found in the intergenic region of CaMV is positioned about 197 bp downstream from the TATA box. Termination of both major RNA transcripts of CaMV occurs just 11 bp downstream from the initial nucleotide of this sequence 30,31. However, a consensus sequence for termination in plants has not been defined. Even the function of AATAAA as a polyadenylation signal in plants is uncertain, since a recent compilation of termination sequences of 26 well characterized plant genes has pointed out that only 39% contain the conventional AATAAA signal 32.

The most extensive and striking region of homology within the large intergenic region of the three viral DNAs occurs downstream of the tentative

Fig. 6. Comparative sequences at the tRNA $_1$ met binding sites of FMV and CaMV. Regions which best complemented the 3' terminus of bean cytoplasmic tRNA $_1$ met 35,36 are shown. Asterisks denote complementarity with the tRNA $_1$ met 3' terminus. The complete sequence of FMV given in Fig. 1 begins with the T residue designated "1" in this figure. The CaMV sequence presented is that of strain CM1841 4 .

polyadenylation signal. This consists of a 35 bp sequence which is virtually identical for the three viral DNAs (Fig. 5). This highly conserved region occurs at position 7228-7262 in the FMV sequence, at 7740-7774 in that of CaMV, and at 7343-7378 of the CERV genome. The conservation of such an extensive tract in the large intergenic region suggests it is of some biological significance.

Probable Primer Binding Sites: Because of similarities in the sizes and positions of coding and noncoding regions of the DNA genomes of FMV and CaMV and evidence for replication of the latter in a reverse transcriptional mode¹⁶,33,34, we sought a tRNA binding site on the FMV plus strand under the assumption that a full length RNA transcript would serve as a template for an RNA dependent DNA polymerase. This search yielded a sequence near the unique minus strand discontinuity (see Fig. 2,6) with complementarity to the 3' end of bean and wheat tRNA₁met35,36. Fifteen of the first 17 nucleotides were found to be complementary to this sequence on the plus DNA strand in the vicinity of the minus strand discontinuity. This sequence is very similar to that postulated to be the minus strand primer for CaMV¹⁶,33,34,37.

In a search of the FMV sequence for plus strand primer binding sites we have used the data of Hull and Donson⁹ as well as our own results¹¹ from mapping of the single stranded breaks. These occur at the approximate nucleotide positions of 1250, 3300 and 5350. Purine-rich regions were found near each of these coordinates. In Fig. 7, we list these sequences and propose a consensus second strand primer binding sequence based on the compilation of 9 such sequences from 4 different caulimoviruses. A notable feature of these tracts is that a pyrimidine-rich region occurs immediately upstream from each run of purine nucleotides.

DISCUSSION

The FMV genome is remarkably similar to that of CaMV and CERV with respect to its size and organization. Its genome consists of 7743 bp (compared to 8031 bp for CaMV DNA 4 and 7932 bp for CERV DNA 17) organized into seven major open reading frames and two intergenic regions.

The sequence reveals that only one strand of the DNA genome (the plus strand) has long open coding regions. Although the complementary strand contains two ORFs which if transcribed would yield proteins in excess of 10 kDa, neither of these regions are conserved in the complementary strand of CaMV or CERV. Furthermore, these ORFs are not preceded by sequences associated with promoter activity. Hence, the transcription of FMV is probably asymmetric like that of the CaMV genome 38,39,40.

A unique ORF (ORF IX) of 313 nucleotides overlaps portions of regions III and IV of the FMV genome (Fig. 2). However, this region is not found in either the CaMV or CERV genomes, and therefore like ORF VIII of CaMV, it may be fortuitous in nature.

The five closely spaced ORFs of the FMV genome, and similar genes of CaMV and CERV raise the question of how these genes are expressed. From knowledge of CaMV it seems likely that genes I-V are transcribed via a genomic length RNA molecule and that no subgenomic versions of these genes will be found (with the possible exception of gene V^{41}).

If a genomic length molecule serves as a mRNA for translation of genes I through V, initiation probably occurs on internal AUGs as proposed by others for $CaMV^{42}$. However, this suggestion conflicts with the scanning hypothesis of Kozak⁴³ for translation in eucaryotes in which only AUGs of 5'-proximal cistrons serve as initiator codons. However, there is now good evidence with mammalian cells that reinitiation occurs if translation is terminated in the

vicinity of internal AUGs⁴⁴,⁴⁵. In fact, translation of caulimoviral genomic length RNA may be one of numerous exceptions to the 5' proximal rule.

Another important difference in the initiation of translation between plants and certain other eucaryotes is that plants probably do not require a particular context of sequence surrounding the initiation codon. A recent compilation of the sequences around the initiation codon of approximately 50 plant genes has revealed that no strongly favored consensus exists⁴⁶.

The presence of short overlaps between the stop of one translational reading region and the beginning of the next may not be an obstacle for efficient internal initiation. An examination of the translation of downstream coding regions of artificially constructed multicistronic transcription units in an SV40 gene vector in mammalian cells has revealed that reach back reinitiation occurs with good efficiency 44. However, the efficiency varies with the distance between the terminator and initiator AUG. This suggests that similar reach back reinitiation may account for translation of FMV ORFs II, IV and V which in each case overlap the 3' end of their upstream cistrons. The initiator AUG of ORF IV, for example, lies 18 nucleotides upstream of the ORF III termination codon. ORF V overlaps ORF IV by 22 nucleotides.

Similarities in the FMV and CaMV genomes extend to the putative primer binding sites of the two viral genomes. A sequence complementary to the 3' end of tRNA₁^{met} occurs in the FMV sequence near or at the single interruption in the minus DNA strand. This suggests an RNA priming event for the initiation of DNA replication like that believed to occur during CaMV DNA replication¹⁶,33,34. The occurrence of this RNA priming site plus the presence of gene V which has much resemblance to known reverse transcriptases²⁶, provides a strong indication that FMV also replicates by reverse transcription.

The highly conserved array of cysteine residues with the CysX₂CysX₄HisX₄Cys motif (Cys-motif) that is present in the nucleic acid binding portion of the gag gene product of retroviruses²⁵ is also observed in the putative gene products of ORF IV in FMV, CaMV³,⁴ and CERV¹⁷. The Cysmotif seems to be a general characteristic in coat protein (precursors) of viruses that are conjectured to use tRNA₁^{met} for the initiation of reverse transcription²⁵. This suggests a dual function of the Cys-motif in encapsidation of genomic RNA and initiation of reverse transcription in immature virions of caulimoviruses⁴⁷. It is notable, for example, that the Cys-motif resembles the metal binding regions in nucleic acid binding

"finger" proteins^{48,49,50}, several of which appear to be important in regulation of transcription⁵¹. Perhaps the Cys-motif has a related function in replication and encapsidation of caulimovirus DNA.

Only a small segment of the FMV ORF VI translation product showed a high degree of homology with the gene VI product of CaMV or CERV (Fig. 4). Except for a short tract of similar amino acid sequence near the N-terminal and a more extensive region near the middle of the gene, there was a very low level of homology in these proteins. Conservation of such a short segment of the amino acid sequence of this gene among caulimoviruses suggests that this region of the protein may be responsible for its molecular function. The more variable regions to either side of this conserved region may interact with the host cell in some manner to establish a compatible host-virus relationship. Gene VI of CaMV has been shown to specify the host reaction during infection and to contain a major host range determinant 52.

Our alignment of the large intergenic sequences of FMV with the other two sequenced caulimoviral DNAs was made by a subjective choice of sequence which best corresponded to the TATA box of CaMV. Other TATA-like sequences are observed in this region including the sequence TCTATAAAATA which starts at nucleotide 7116. The chosen alignment, shown graphically in Fig. 5, revealed a conserved 35 bp intergenic sequence in a nearby downstream region. An almost exact sequence occurs in the same position in CaMV and CERV DNA. The conserved 35 bp sequence in the large intergenic region of the caulimoviruses occurs downstream of the termination site of the 35S and 19S RNAs of CaMV (at nucleotide 7615). Since downstream sequences are known to be involved in transcriptional termination in eucaryotes³², this suggests a possible function for the 35 bp sequence.

ACKNOWLEDGEMENTS

The authors wish to thank Susan Ballard for preparing many of the sequencing templates and Roger Hull for supplying the sequence of carnation etched ring virus DNA before its publication. We would also like to express our appreciation to Dr. Les Domier for his assistance in doing the computer assisted amino acid alignments. This research was supported by the U.S. Department of Agriculture CGO grants 85-CRCR-1-1743 and 86-CRCR-1-2261. The authors are also grateful for the support and facilities provided by Kentucky State THRI project no. 5-41086.
